Abstract

The systematics of the giant dipole resonance (GDR) widths in hot and rotating nuclei are studied in terms of temperature T , angular momentum J and mass A . The different experimental data in the temperature range of 1 - 2 MeV have been compared with the thermal shape fluctuation model (TSFM) in the liquid drop formalism using a modified approach to estimate the average values of T , J and A in the decay of the compound nucleus. The values of the ground state GDR widths have been extracted from the TSFM parametrization in the liquid drop limit for the corrected T , J and A for a given system and compared with the corresponding available systematics of the experimentally measured ground state GDR widths for a range of nuclei from $A = 45$ to 194. Amazingly, the nature of the theoretically extracted ground state GDR widths matches remarkably well, though 1.5 times smaller, with the experimentally measured ground state GDR widths consistently over a wide range of nuclei.

INTRODUCTION

The collective excitations in nuclei, in particular, the giant dipole resonance (GDR) have been studied in great detail over the years to understand the complex quantal nuclear many body systems. The phenomenon of GDR oscillations in nuclei, has been studied extensively in cold as well as in hot and fast rotating nuclei. In the case of GDR vibrations in cold nuclei, i.e. for the case of GDR built on nuclear ground state, very well established systematics for the resonance energy and its width as a function of nuclear mass exist. The understanding of the mechanism for such a large width of the resonance is of particular importance as it gives an insight into the strong damping mechanism of the collective dipole oscillations in nuclei. A systematic study of the resonance widths at higher temperatures in nuclei in the cases of GDR built on excited states gives us clues regarding the damping mechanisms in hot nuclei and the interplay of the temperature and angular momentum effects. In a particular nucleus, the resonance energy remains more or less constant but its width (or FWHM) increases as the temperature or the excitation energy of the nucleus increases. There had been a lot of experimental [1, 2, 3, 4, 5] as well as theoretical [6, 7] activities to understand this increase of the GDR width with temperature in the past years. The main experimental approach had been the heavy ion fusion reactions populating the compound nucleus at different excitations and spins. The temperature dependence of the GDR width to some extent has been explained in terms of adiabatic, large amplitude thermal fluctuations of the nuclear shape – the thermal shape fluctuation model (TSFM). Though TSFM is successful to some extent, (in the temperature range 1 - 2 MeV and for low spins) it does not explain the results of [5, 8, 9, 10], particularly those at the lowest T (near T=1.0 MeV) for ^{120}Sn .

In the past there have been several attempts to understand the global features of the temperature and spin dependence of the measured GDR widths in a comprehensive manner, by parametrizing the GDR widths in terms of the relevant macroscopic parameters, i.e. temperature, angular momentum, nuclear mass etc. [11, 12, 13]. The most notable among them is the work of Kusnezov et al [14] in which the GDR width $\Gamma(T, J, A)$ at a finite temperature (T) and spin (J) is parametrized in terms of a reduced width, from a liquid drop (LD) free energy consideration,

$$\Gamma_{red} = \left[\frac{\Gamma_{exp}(T, J, A)}{\Gamma(T, J = 0, A)} \right]^{\frac{T+3T_0}{4T_0}} = 1 + \frac{1.8}{[1 + e^{(1.3-\xi)/0.2}]} \quad (1)$$

where, $\Gamma_{exp}(T, J, A)$ is the experimental width, the reduced scaling parameter $\xi = J/A^{5/6}$ and

$$\Gamma(T, J = 0, A) = \left(6.45 - \frac{A}{100}\right) \ln \left(1 + \frac{T}{T_0}\right) + \Gamma_0(A) \quad (2)$$

According to the authors, $\Gamma_0(A)$ is usually extracted from the measured ground state GDR and T_0 is taken as a reference temperature ($=1$ MeV). Surprisingly, they used a value of $\Gamma_0 = 3.8$ MeV for ^{120}Sn and ^{208}Pb data (after recalculating the nuclear temperatures) which was smaller than an earlier description (5 MeV) [7]. For other nuclei the authors themselves and others [8, 9, 10] used the same parametrization with a wider range of values for Γ_0 (2.5 - 5.2 MeV), which were less than the ground state values, for describing the experimental GDR widths at different temperatures and spins. This simple parametrization, however failed to explain the data at low temperature and highest spins.

The important points, as they stand now, for the explanation of the temperature dependence of the GDR width in general and particularly within the framework of TSFM in the LD regime, are 1) a proper characterization of the nuclear temperature as shown by Kelly and others [4] and 2) using a proper Γ_0 parameter in a uniform way throughout the nuclear mass, temperature and angular momentum range. Lately, there have been attempts, [9] to properly characterize the nuclear temperature in a heavy ion fusion reaction. In this paper we have tried to estimate the proper nuclear temperature for the GDR γ -emission in heavy ion fusion - CN γ -decay experiments for our recent measurements [15] as well as for other published results [8, 9, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30] in a unified treatment and compared them in the light of TSFM calculations of Kusnezov et al with a uniform description of the Γ_0 parameter in accordance with the measured systematics of the ground state GDR widths over the entire nuclear mass range.

The same procedure is adopted while explaining our recently measured GDR widths in ^{113}Sb populated with high angular momenta ($\leq 60 \hbar$) and at temperatures ≤ 2 MeV [15] using a $\Gamma_0 = 3.8$ MeV.

DATA ANALYSIS

In heavy ion fusion - evaporation reactions, high energy γ -photons are emitted from various stages of the decay cascade. At high excitation energies, the compound nucleus decays through a large number of steps and therefore, the excitation energy (E^*), angu-

lar momentum (J), mass (A) and charge (Z) should be averaged over all the decay steps. The average values of E^* , J , A and Z should be different and less than those of the initial compound nucleus. While most authors consider an average temperature $\langle T \rangle$ for the corresponding measured GDR widths, the averaging of J , A and Z has not been addressed to. Though the averaging of A and Z does not change significantly the representation, the same is not true for J , since a small change in $\langle J \rangle$ modifies the representation of the data in terms of reduced parameters in Kusnezov's description of TSFM [9]. Two basic approaches are generally taken in the existing literatures for the estimation of $\langle T \rangle$ for the GDR γ -emission in a compound nucleus. In the first, $\langle T \rangle = [d \ln(\rho)/dE]^{-1}$ is evaluated at $E^* = E_{CN} - \langle E_{rot} \rangle - E_{GDR} - \Delta_p$, where E_{CN} is the initial CN excitation energy, $\langle E_{rot} \rangle$ is the average rotational energy computed at the mean J of the experimental J distribution and Δ_p is the pairing energy. This procedure is incorrect since there is no averaging over E^* in the CN decay chain. In the other approach, the average temperature is estimated as, $\langle T \rangle = [(\langle E^* \rangle - \langle E_{rot} \rangle - E_{GDR} - \Delta_p)/a(\langle E^* \rangle)]^{1/2}$, where $a(\langle E^* \rangle)$ is the energy dependent level density parameter. In this case, though the averaging is done over all the decay steps, $\langle E_{rot} \rangle$ is calculated for the mean J of the initial CN. It is also not proper to include each step in the CN decay chain for the averaging. Instead, only that part contributing to the GDR γ -emission [17] in the decay cascade should be taken for averaging, thereby, setting a lower limit for the excitation energy in the CN decay cascade. Recently, Wieland et al [17] used the same procedure of averaging over a part of the decay cascade in their analysis of highly excited ^{132}Ce data for a re-estimation of temperature of the nucleus emitting GDR photons. We have followed this second scheme of averaging to recalculate the average parameters in our work. This lower limit in the excitation energy amounts to approximately 50% of the total high energy γ -yield in the CN decay chain and does not affect the GDR γ -rays in the region $E_\gamma = 12 - 25$ MeV. $\langle E_{rot} \rangle$ is evaluated with the average J ($\langle J \rangle$), re-estimated using the above mentioned lower limit in E^* . $\langle E^* \rangle$ is calculated by averaging E^* with corresponding weights over the daughter nuclei in the CN decay cascade for the γ -emission in the GDR energy range 12 - 25 MeV, $\langle E^* \rangle = \sum_i (E_i^* \omega_i) / \sum_i \omega_i$, where E_i^* is the excitation energy of the i -th nucleus in the decay cascade and ω_i is the corresponding yield in the GDR energy region 12 - 25 MeV. The corresponding $\langle A \rangle$ and $\langle Z \rangle$ are calculated in the same way. Fig.1 demonstrates the effect of averaging over the part of the decay cascade on the GDR strength distribution for the excited ^{113}Sb nucleus at an initial excitation energy and angular

FIG. 1: The top panel shows the CASCADE predictions for ^{113}Sb populated at 122 MeV excitation and $60\hbar$ spin, with an averaging over the full (100%) (symbols) and part (50%) (line) of the decay cascade. The bottom panel shows the divided plots for the corresponding GDR strength distributions.

momentum of 122 MeV and $\sim 60 \hbar$ respectively. It is clear that this averaging leaves the GDR strengths and high energy photon emissions unchanged, except at very low energies without affecting the width. The CN particle evaporation widths (Γ_{ev}) have been incorporated in the TSFM calculation for the temperature dependence of the GDR widths to take into consideration the effect of evaporation of particles and the corresponding energy loss before the GDR γ -emission in the CN decay chain. The Γ_{ev} is calculated using the modified statistical model code CASCADE [31] and folded with the GDR width parameter (Γ_0) in TSFM calculation. In this low temperature region ($T \leq 2$ MeV and with $\tilde{a} = A/8.0$), the particle decay width is rather small (~ 0.2 MeV at $T = 2.0$ MeV) and its inclusion within the TSFM marginally improves the prediction.

The same procedure has been used for the estimation of $\langle T \rangle$ and $\langle J \rangle$ for nuclei in the broad mass range of 45 - 194 and temperature range of 1 - 2 MeV (shown in tables I, II and III). All calculations have been done with a modified version of the statistical model code CASCADE [31]. In almost all the nuclei, we have adopted Ignatuyk-Reisdorf level density

FIG. 2: The measured GDR widths at different extracted average temperatures are plotted for various nuclei studied. The solid lines are the predictions of the TSFM calculations for different average angular momenta. The shaded curves show the change in the calculation for different J values.

prescription [32, 33] keeping the asymptotic level density parameter $\tilde{a} = A/8 \text{ MeV}^{-1}$, except in the case of ^{86}Mo . The level density parameter for ^{86}Mo [8] was measured experimentally and was kept fixed at $\tilde{a}=A/7.5 \text{ MeV}^{-1}$ as suggested by the authors. The sensitivity of the average values has been checked by changing the parameter $\tilde{a}$ from $A/8$ to $A/9$, resulting in a change in $\langle T \rangle \leq 5\%$ without affecting $\langle J \rangle$ and is less than the experimental uncertainties in measuring GDR widths. Thus it is clear that the extracted average quantities do not change much due to uncertainties in the level density parameters.

The calculations were done for all the data points following the prescription just described in the framework of TSFM for the LD regime as suggested by Kusnezov et al. The parameter Γ_0 was extracted for each of the nuclei studied by simultaneously fitting the measured GDR widths at the recalculated $\langle T \rangle$ for various ranges of $\langle J \rangle$ (as shown in Fig.2) and the reduced GDR widths Γ_{red} at the recalculated reduced parameter $\langle J \rangle / A^{5/6}$ for different temperatures (as shown in Fig.3). Almost all the data points follow the respective calculations quite well. The extracted Γ_0 values for different nuclei are plotted against the corresponding mass

FIG. 3: The reduced GDR widths are plotted against the reduced parameter $\xi = J/A^{5/6}$ for different nuclei and grouped in different panels so that the data points from different nuclei show a minimum overlap. The references for the corresponding data points are indicated alongside the legends in the respective plots.

numbers and are shown in Fig.4 alongwith the measured ground state values of the GDR widths (open circles) [2, 34, 35]. It is clear from Fig.4 that the nature of the dependence of the extracted Γ_0 values at different nuclear masses matches remarkably well with the measured ground state GDR values. For comparison with the ground state GDR widths, the extracted Γ_0 values were multiplied by a factor of 1.5. The Γ_0 parameter in Kusnezov's formalism is interpreted as "the width for a spherical shape". It is clear from the present representation that these Γ_0 values exactly follow the mass dependence of the measured ground state GDR widths, reproducing even the effects of shell closure and nuclear shapes. The discrepancies mentioned in Ref.[9] for the ^{147}Eu and ^{154}Dy nuclei after re-analysis by the authors match quite well in this case. Except for one particular data point for ^{154}Dy [30] at the highest angular momentum ($J=50\hbar$) (shown as an open circle in the middle panel of Fig.3) the corresponding GDR width seems quite large than the predicted systematics. This could be due to a rotation induced large change in the shape of the nucleus at high excitation. The extracted Γ_0 matches remarkably well with the ground state systematics

FIG. 4: The calculated Γ_0 values are compared with the measured ground state GDR widths (open circles) (taken from refs. [2, 34, 35]) as a function of the nuclear mass numbers. The extracted Γ_0 values are also plotted (filled symbols) after multiplying by a factor of 1.5.

though. The cases of ^{86}Mo and ^{120}Sn are particularly interesting. In the case of ^{86}Mo the analysis reported in Ref[5] uses J_{CN} for calculating E_{rot} and for Kusnezov's representation. Although, later, an averaging over the entire CN decay chain was done [9] for evaluating $\langle J \rangle$ improving the agreement with TSFM. However, the same approach could not explain the data for ^{110}Sn . Our unified approach (averaging over a part of the decay chain for evaluating E^* , J , A , Z) along with a proper choice of Γ_0 explains both the data throughout. In the case of ^{120}Sn , however, our averaging along with the corresponding Γ_0 values in accordance with the experimental ground state GDR width improves the fit overall except the points at the lowest temperatures (around $T \sim 1$ MeV). It is surprising, though, the measured width at around $T \sim 1$ MeV is smaller than that at $T = 0$ MeV, the experimental ground state GDR width.

The method of averaging adopted in this work, in a unified way, applied over a range of nuclei, is more appropriate for nuclei populated with a large angular momentum and excitation energy. Table IV shows the extracted average values for the two nuclei ^{86}Mo and ^{113}Sb populated at the two extremes of excitation energy and angular momentum within our data samples, with a partial and a full average over the decay cascade. The extracted Γ_0 values obtained from a simultaneous description of the dependence of experimental GDR widths in terms of $\langle T \rangle$ and $\langle J \rangle / A^{5/6}$ (obtained with a partial average over the decay cascade) match quite well with the systematic dependence of experimental ground state GDR widths as a function of nuclear mass (A).

SUMMARY AND CONCLUSION

In conclusion, we have studied the systematics of the GDR widths at different spins and particularly in the temperature range of 1 - 2 MeV over a broad range of nuclear masses in the framework of the liquid drop thermal shape fluctuation theory. The phenomenological description given by Kusnezov et al [14] describes quite well all the data from various experiments done earlier even at low temperature and highest spins, provided the temperature and the angular momentum of the decaying nucleus populated in such a heavy ion reaction is characterized properly using the averaging procedure discussed here and using a Γ_0 parameter which is 1.5 times smaller than the ground state GDR width for that particular nucleus. The extracted values of Γ_0 match exactly in shape and form (apart from a normalization factor of 1.5) with the measured systematics of the ground state GDR widths in spite of using a thermal fluctuation model in the liquid drop limit. The reason remains an interesting question to investigate.
